L15: statistical clustering

Similarity measures
Criterion functions
Cluster validity
Flat clustering algorithms
  – k-means
  – ISODATA
Hierarchical clustering algorithms
  – Divisive
  – Agglomerative
Non-parametric unsupervised learning

In L14 we introduced the concept of unsupervised learning

– A collection of pattern recognition methods that “learn without a teacher”
– Two types of clustering methods were mentioned: parametric and non-parametric

Parametric unsupervised learning

– Equivalent to density estimation with a mixture of (Gaussian) components
– Through the use of EM, the identity of the component that originated each data point was treated as a missing feature

Non-parametric unsupervised learning

– No density functions are considered in these methods
– Instead, we are concerned with finding natural groupings (clusters) in a dataset

Non-parametric clustering involves three steps

– Defining a measure of (dis)similarity between examples
– Defining a criterion function for clustering
– Defining an algorithm to minimize (or maximize) the criterion function
Proximity measures

Definition of metric

- A measuring rule \( d(x, y) \) for the distance between two vectors \( x \) and \( y \) is considered a metric if it satisfies the following properties

\[
\begin{align*}
    d(x, y) &\geq d_0 \\
    d(x, y) = d_0 &\text{ if } x = y \\
    d(x, y) = d(y, x) \\
    d(x, y) &\leq d(x, z) + d(z, y)
\end{align*}
\]

- If the metric has the property \( d(ax, ay) = |a|d(x, y) \) then it is called a norm and denoted \( d(x, y) = \|x - y\| \)

The most general form of distance metric is the power norm

\[
\|x - y\|_{p/r} = \left( \sum_{i=1}^{D} |x_i - y_i|^p \right)^{1/r}
\]

- \( p \) controls the weight placed on any dimension dissimilarity, whereas \( r \) controls the distance growth of patterns that are further apart

- Notice that the definition of norm must be relaxed, allowing a power factor for \( |a| \)

[Marques de Sá, 2001]
Most commonly used metrics are derived from the power norm

- Minkowski metric ($L_k$ norm)
  \[ \|x - y\|_k = \left( \sum_{i=1}^{D} |x_i - y_i|^k \right)^{1/k} \]
  - The choice of an appropriate value of $k$ depends on the amount of emphasis that you would like to give to the larger differences between dimensions

- Manhattan or city-block distance ($L_1$ norm)
  \[ \|x - y\|_{c-b} = \sum_{i=1}^{D} |x_i - y_i| \]
  - When used with binary vectors, the L1 norm is known as the Hamming distance

- Euclidean norm ($L_2$ norm)
  \[ \|x - y\|_e = \left( \sum_{i=1}^{D} |x_i - y_i|^2 \right)^{1/2} \]

- Chebyshev distance ($L_\infty$ norm)
  \[ \|x - y\|_c = \max_{1 \leq i \leq D} |x_i - y_i| \]
Other metrics are also popular

- Quadratic distance
  \[ d(x, y) = \sqrt{(x - y)^T B (x - y)} \]
  - The Mahalanobis distance is a particular case of this distance

- Canberra metric (for non-negative features)
  \[ d_{ca}(x, y) = \sum_{i=1}^{D} \frac{|x_i - y_i|}{x_i + y_i} \]

- Non-linear distance
  \[ d_N(x, y) = \begin{cases} 
  0 & \text{if } d_e(x, y) < T \\
  H & \text{o.w.} \end{cases} \]
  - where \( T \) is a threshold and \( H \) is a distance
  - An appropriate choice for \( H \) and \( T \) for feature selection is that they should satisfy
    \[ H = \frac{\Gamma \left( \frac{p}{2} \right)}{T^p 2\pi^{p/2}} \]
    - and that \( T \) satisfies the unbiasedness and consistency conditions of the Parzen estimator: \( T^P N \to \infty, T \to 0 \) as \( N \to \infty \)

[Webb, 1999]
The above distance metrics are measures of **dissimilarity**

Some measures of **similarity** also exist

- Inner product
  \[ s_{INNER}(x, y) = x^T y \]
  - The inner product is used when the vectors \( x \) and \( y \) are normalized, so that they have the same length

- Correlation coefficient
  \[ s_{CORR}(x, y) = \frac{\sum_{i=1}^{D} (x_i - \bar{x})(y_i - \bar{y})}{\left[ \sum_{i=1}^{D} (x_i - \bar{x})^2 \sum_{i=1}^{D} (y_i - \bar{y})^2 \right]^{1/2}} \]

- Tanimoto measure (for binary-valued vectors)
  \[ s_T(x, y) = \frac{x^T y}{|x|^2 + |y|^2 - x^T y} \]
Criterion function for clustering

Once a (dis)similarity measure has been determined, we need to define a criterion function to be optimized

- The most widely used clustering criterion is the sum-of-square-error

\[
J_{MSE} = \sum_{i=1}^{C} \sum_{x \in \omega_i} |x - \mu_i|^2 \quad \text{where} \quad \mu_i = \frac{1}{N_i} \sum_{x \in \omega_i} x
\]

- This criterion measures how well the data set \( X = \{x^{(1)} \ldots x^{(N)}\} \) is represented by the cluster centers \( \mu = \{\mu^{(1)} \ldots \mu^{(C)}\} (C < N) \)

- Clustering methods that use this criterion are called minimum variance

- Other criterion functions exist, based on the scatter matrices used in Linear Discriminant Analysis

  - For details, refer to [Duda, Hart and Stork, 2001]
Cluster validity

The validity of the final cluster solution is highly subjective

- This is in contrast with supervised training, where a clear objective function is known: Bayes risk
- Note that the choice of (dis)similarity measure and criterion function will have a major impact on the final clustering produced by the algorithms

Example

- Which are the meaningful clusters in these cases?
- How many clusters should be considered?

- A number of quantitative methods for cluster validity are proposed in [Theodoridis and Koutrombas, 1999]
Iterative optimization

Once a criterion function has been defined, we must find a partition of the data set that minimizes the criterion

- Exhaustive enumeration of all partitions, which guarantees the optimal solution, is unfeasible
  - For example, a problem with 5 clusters and 100 examples yields $10^{67}$ partitionings

The common approach is to proceed in an iterative fashion

1) Find some reasonable initial partition and then
2) Move samples from one cluster to another in order to reduce the criterion function

These iterative methods produce sub-optimal solutions but are computationally tractable

We will consider two groups of iterative methods

- Flat clustering algorithms
  - These algorithms produce a set of disjoint clusters
  - Two algorithms are widely used: k-means and ISODATA

- Hierarchical clustering algorithms:
  - The result is a hierarchy of nested clusters
  - These algorithms can be broadly divided into agglomerative and divisive approaches
The k-means algorithm

Method

– k-means is a simple clustering procedure that attempts to minimize the criterion function $J_{MSE}$ in an iterative fashion

$$J_{MSE} = \sum_{i=1}^{C} \sum_{x \in \omega_i} |x - \mu_i|^2$$

where $\mu_i = \frac{1}{N_i} \sum_{x \in \omega_i} x$

1. Define the number of clusters
2. Initialize clusters by
   - an arbitrary assignment of examples to clusters or
   - an arbitrary set of cluster centers (some examples used as centers)
3. Compute the sample mean of each cluster
4. Reassign each example to the cluster with the nearest mean
5. If the classification of all samples has not changed, stop, else go to step 3

– It can be shown (L14) that k-means is a particular case of the EM algorithm for mixture models
Vector quantization

- An application of k-means to signal processing and communication
- Univariate signal values are usually quantized into a number of levels
  - Typically a power of 2 so the signal can be transmitted in binary format
- The same idea can be extended for multiple channels
  - We could quantize each separate channel
  - Instead, we can obtain a more efficient coding if we quantize the overall multidimensional vector by finding a number of multidimensional prototypes (cluster centers)
  - The set of cluster centers is called a codebook, and the problem of finding this codebook is normally solved using the k-means algorithm
ISODATA

Iterative Self-Organizing Data Analysis (ISODATA)

- An extension to the k-means algorithm with some heuristics to automatically select the number of clusters

ISODATA requires the user to select a number of parameters

- $N_{MIN\_EX}$ minimum number of examples per cluster
- $N_D$ desired (approximate) number of clusters
- $\sigma^2_S$ maximum spread parameter for splitting
- $D_{MERGE}$ maximum distance separation for merging
- $N_{MERGE}$ maximum number of clusters that can be merged

The algorithm works in an iterative fashion

1) Perform k-means clustering
2) Split any clusters whose samples are sufficiently dissimilar
3) Merge any two clusters sufficiently close
4) Go to 1)
1. Select an initial number of clusters $N_C$ and use the first $N_C$ examples as cluster centers $\mu_k, k = 1..N_C$
2. Assign each example to the closest cluster
   a. Exit the algorithm if the classification of examples has not changed
3. Eliminate clusters that contain less than $N_{MIN\_EX}$ examples and
   a. Assign their examples to the remaining clusters based on minimum distance
   b. Decrease $N_C$ accordingly
4. For each cluster $k$,
   a. Compute the center $\mu_k$ as the sample mean of all the examples assigned to that cluster
   b. Compute the average distance between examples and cluster centers
      \[ d_{avg} = \frac{1}{N} \sum_{k=1}^{N_C} N_k d_k \] and
      \[ d_k = \frac{1}{N_k} \sum_{x \in \omega_k} |x - \mu_k| \]
   c. Compute the variance of each axis and find the axis $n^*$ with maximum variance $\sigma_k^2(n^*)$
5. For each cluster $k$ with $\sigma_k^2(n^*) > \sigma_S^2$, if $d_k > d_{AVG}$ and $N_k > 2N_{MIN\_EX} + 1$ or $\{NC < ND/2\}$
   a. Split that cluster into two clusters where the two centers $\mu_k1$ and $\mu_k2$ differ only in the coordinate $n^*$
      i. $\mu_k1(n^*) = k(n^*) + \varepsilon k(n^*)$ (all other coordinates remain the same, $0 < \varepsilon < 1$)
      ii. $\mu_k2(n^*) = k(n^*) - \varepsilon k(n^*)$ (all other coordinates remain the same, $0 < \varepsilon < 1$)
   b. Increment $N_C$ accordingly
   c. Reassign the cluster’s examples to one of the two new clusters based on minimum distance to cluster centers
6. If $N_C > 2ND$ then
   a. Compute all distances $D_{ij} = d(\mu_i, \mu_j)$
   b. Sort $D_{ij}$ in decreasing order
   b. For each pair of clusters sorted by $D_{ij}$, if (1) neither cluster has been already merged, (2) $D_{ij} < D_{MERGE}$
      and (3) not more than $N_{MERGE}$ pairs of clusters have been merged in this loop, then
      i. Merge $i$th and $j$th clusters
      ii. Compute the cluster center $\mu' = \frac{N_i \mu_i + N_j \mu_j}{N_i + N_j}$
      iii. Decrement $N_C$ accordingly
8. Go to step 1

[Therrien, 1989]
ISODATA has been shown to be an extremely powerful heuristic
Some of its advantages are

– Self-organizing capabilities
– Flexibility in eliminating clusters that have very few examples
– Ability to divide clusters that are too dissimilar
– Ability to merge clusters that are sufficiently similar

However, it suffers from the following limitations

– Data must be linearly separable (long narrow or curved clusters are not handled properly)
– It is difficult to know a priori the “optimal” parameters
– Performance is highly dependent on these parameters
– For large datasets and large number of clusters, ISODATA is less efficient than other linear methods
– Convergence is unknown, although it appears to work well for non-overlapping clusters

In practice, ISODATA is run multiple times with different values of the parameters and the clustering with minimum SSE is selected
Hierarchical clustering

k-means and ISODATA create disjoint clusters, resulting in a flat data representation

– However, sometimes it is desirable to obtain a hierarchical representation of data, with clusters and sub-clusters arranged in a tree-structured fashion
– Hierarchical representations are commonly used in the sciences (e.g., biological taxonomy)

Hierarchical clustering methods can be grouped in two general classes

– Agglomerative
  • Also known as bottom-up or merging
  • Starting with N singleton clusters, successively merge clusters until one cluster is left

– Divisive
  • Also known as top-down or splitting
  • Starting with a unique cluster, successively split the clusters until N singleton examples are left
Dendrograms

A binary tree that shows the structure of the clusters

- Dendrograms are the preferred representation for hierarchical clusters
  - In addition to the binary tree, the dendrogram provides the similarity measure between clusters (the vertical axis)
- An alternative representation is based on sets
  
  \[
  \{\{x_1, \{x_2, x_3\}\}, \{\{x_4, x_5\}, \{x_6, x_7\}\}, x_8\}\]

  - However, unlike the dendrogram, sets cannot express quantitative information
Divisive clustering

Define

- $N_C$ Number of clusters
- $N_{EX}$ Number of examples

How to choose the “worst” cluster

- Largest number of examples
- Largest variance
- Largest sum-squared-error...

How to split clusters

- Mean-median in one feature direction
- Perpendicular to the direction of largest variance...

The computations required by divisive clustering are more intensive than for agglomerative clustering methods

- For this reason, agglomerative approaches are more popular

1. Start with one large cluster
2. Find “worst” cluster
3. Split it
4. If $N_C < NEX$ go to 2
Agglomerative clustering

Define

- \( N_C \)  Number of clusters
- \( N_{EX} \)  Number of examples

1. Start with \( N_{EX} \) singleton clusters
2. Find nearest clusters
3. Merge them
4. If \( N_C > 1 \) go to 2

How to find the “nearest” pair of clusters

- Minimum distance
  \[
  d_{\text{min}}(\omega_i, \omega_j) = \min_{x \in \omega_i, y \in \omega_j} \|x - y\|
  \]

- Maximum distance
  \[
  d_{\text{max}}(\omega_i, \omega_j) = \max_{x \in \omega_i, y \in \omega_j} \|x - y\|
  \]

- Average distance
  \[
  d_{\text{avg}}(\omega_i, \omega_j) = \frac{1}{N_i N_j} \sum_{x \in \omega_i} \sum_{y \in \omega_j} \|x - y\|
  \]

- Mean distance
  \[
  d_{\text{mean}}(\omega_i, \omega_j) = \|\mu_i - \mu_j\|
  \]
Minimum distance

– When $d_{\text{min}}$ is used to measure distance between clusters, the algorithm is called the nearest-neighbor or single-linkage clustering algorithm
– If the algorithm is allowed to run until only one cluster remains, the result is a minimum spanning tree (MST)
– This algorithm favors elongated classes

Maximum distance

– When $d_{\text{max}}$ is used to measure distance between clusters, the algorithm is called the farthest-neighbor or complete-linkage clustering algorithm
– From a graph-theoretic point of view, each cluster constitutes a complete sub-graph
– This algorithm favors compact classes

Average and mean distance

– $d_{\text{min}}$ and $d_{\text{max}}$ are extremely sensitive to outliers since their measurement of between-cluster distance involves minima or maxima
– $d_{\text{ave}}$ and $d_{\text{mean}}$ are more robust to outliers
– Of the two, $d_{\text{mean}}$ is more attractive computationally
  • Notice that $d_{\text{ave}}$ involves the computation of $N_i N_j$ pairwise distances
Example

- Perform agglomerative clustering on $X$ using the single-linkage metric

$$X = \{1, 3, 4, 9, 10, 13, 21, 23, 28, 29\}$$

- In case of ties, always merge the pair of clusters with the largest mean
- Indicate the order in which the merging operations occur
\[ d_{\text{min}} \text{ vs. } d_{\text{max}} \]
